# 1 Introduction

## 1.1 Overview

The use of pain intensity cut-offs for study inclusion in clinical trials has two consequences. Firstly, the cut-off artificially raises the baseline mean pain score of the cohort being studied compared to the population the cohort was sampled from. Secondly, unless the correlation between two sequential measurements is 1, there should be a “flattening” of the relationship between the first and subsequent measurements. This “flattening” means that the cut-off has a disproportionate effect on the mean baseline pain intensity compared to subsequent measurements.

This script demonstrates the effect of this “flattening” of the relationship between two sequential pain measurements in a hypothetical placebo group in a clinical trial for the management of pain in the presence of various pain intensity cut-off values for trial inclusion.

## 1.2 Modelling specifics

### 1.2.1 Data simulation parameters

Baseline pain scores were extracted from papers listed in the supplementary materials of a systematic review of pharmacological treatments for neuropathic pain<sup>1</sup> and that did not include baseline pain threshold inclusion criteria. Using this information, the upper bound of the 95% confidence interval of the pooled mean pain intensity at baseline was calculated to be 6.7 on an 11-point numerical pain rating scale (NRS), and the pooled SD of pain intensity at baseline was 1.7. The correlation between measurements 1 (V1) and 2 (V2) was set at 0.51 and 0.37 based on aggregated data across five clinical trials from 788 patients with rheumatoid arthritis for baseline vs week 4 and week 12 of the trial, respectively<sup>2</sup>, and 0.26 based on aggregated data across nine clinical trials from 2017 patients with knee or hip arthritis or chronic low back pain for baseline vs week 12 of the trial<sup>3</sup>.

### 1.2.2 Data simulation and processing

Covariance matrices were generated for each of the three combinations of correlation ( $r = 0.26, 0.37$ , or  $0.51$ ) and the SD (1.7) using the `cor2cov` function from the **MBESS** package<sup>4</sup>. Then, each of the three covariance matrices was used to

<sup>4</sup>Kelley K. MBESS: The MBESS R package. 2019. Available: <https://CRAN.R-project.org/package=MBESS>

a generate random sample from a bivariate normal distribution ( $n = 1000$  per sample) with a mean of 6.7. The samples were generated using the `mvrnorm` function from the `MASS` package<sup>5</sup>.

To check the data once they had been generated, measurement 1 (V1) and measurement 2 (V2) were plotted against each other using scatterplots with marginal density plots, and the sample means and SDs were calculated, as was the correlation between the two samples (*unconstrained data*). Thereafter, values were filtered (constrained) such that the minimum V1 value was 1 and the minimum V2 value was 0 on an 11-point NRS, and the maximum V1 and V2 values were 10 on an 11-point NRS. The minimum value of V1 was set to 1 because volunteers eligible to enter a placebo-controlled clinical trial can be expected to have at least some pain. In comparison, V2 values were unconstrained and could take any value from 0 to 10 because pain intensity may take values across the full range of the scale on follow-up. Maximum pain rating were limited to values of 10, the upper limit of the rating scale. To check for changes in centrality, spread, and correlation after filtering the data, the data were once again assessed using plots and numeric summaries.

### 1.2.3 Modelling the effect of baseline pain inclusion thresholds

A baseline inclusion threshold of 0 on an 11-point NRS (i.e., no inclusion threshold) was used as a “control”. In addition to the control threshold, three baseline pain intensity inclusion thresholds were selected based on the data listed in the supplementary materials of Finnerup and colleagues<sup>1</sup>. The three thresholds were: pain intensity  $\geq 4$  (71% of listed studies), pain intensity  $\geq 3$  (12% of listed studies), and pain intensity  $\geq 5$  (11% of listed studies). Data from the three simulated datasets (mean = 6.7, SD = 1.7, correlation = 0.26, 0.37, 0.51) were each modelled under each of the four baseline pain intensity inclusion thresholds.

Modelling the effect of the thresholds involved removing all pairs of V1 and V2 data where V1 was less than the threshold value, yielding new datasets V1' and V2'. To assess the effect of removing data pairs on the group means, we calculated the difference in group means between V1 and V1', and V2 and V2'. To assess the magnitude of the effect, we calculated the mean difference in pain intensity scores between V1' and V2' (point estimate), and generated bias-corrected and accelerated 95% bootstrapped confidence intervals of the difference (2000 resamples, generated using the `groupwiseMean` function from the `rcompanion` package<sup>6</sup>).

For reproducibility, I set the random seed to “2019” for all random sampling.

Note: Because of random sampling the mean (SD) of the samples differ slightly from the population mean (SD).

## 2 Generate 2x2 covariance matrices

Generate a covariance matrix using an SD of 1.7 and correlation of:

- $r = 0.26$  (Scenario 5A)
- $r = 0.37$  (Scenario 5B)
- $r = 0.51$  (Scenario 5C)

```
# Generate 2*2 correlation matrices
cor_026 <- matrix(c(1, 0.26, 0.26, 1), ncol = 2)
cor_037 <- matrix(c(1, 0.37, 0.37, 1), ncol = 2)
cor_051 <- matrix(c(1, 0.51, 0.51, 1), ncol = 2)

# Set the standard deviation
std <- c(1.7, 1.7)

# Generate a 2*2 covariance matrices
cov_026 <- cor2cov(cor.mat = cor_026,
                  sd = std)
cov_037 <- cor2cov(cor.mat = cor_037,
                  sd = std)
cov_051 <- cor2cov(cor.mat = cor_051,
                  sd = std)
```

### 3 Scenario 5A: Inter-measurement correlation = 0.26

#### 3.1 Generate and summarise data

##### 3.1.1 Unconstrained data
